(Received 18 June 1999)

An account is presented of our studies of the order-disorder phase transitions in  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ . These are based on parameter-free interionic potentials based on the Gordon-Kim modified electron-gas formalism extended to molecular ions. We performed static structural relaxations and supercell molecular dynamics and predicted with reasonable accuracy the temperatures for the onset of the transitions. In particular, we address the question of how the  $\text{N}_3^-$  ions reorient to yield the transitions. We found the existence of NaCl-type high-temperature phases in disordered  $\text{KN}_3$  and  $\text{RbN}_3$  and argue that this restructuring is preempted by melting in these two systems. [S0163-1829(99)10541-1]

## I. INTRODUCTION

Alkali azides, salts with linear  $\text{N}_3^-$  anions, have been extensively studied in recent years.<sup>1</sup> The majority of alkali azides exhibit simple spatial symmetry, but since they have an internal molecular structure, they are logical candidates to study, following alkali halides and cyanides ( $\text{CN}^-$ ). Of special interest, from the theoretical point of view, is the order-disorder phase transition observed in most of these systems before melting. In particular, there exists a substantial disagreement on the microscopic mechanism of these transitions.<sup>1</sup> In order to address this question we present results of a molecular-dynamics (MD) study performed on three isostructural azides,  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ . In particular, we investigate how the dynamics of the  $\text{N}_3^-$  molecular ions drives the phase transformations in these materials.

In prior work,<sup>2</sup> we have developed a first-principles model, based on the Gordon-Kim (GK) modified electron-gas formalism,<sup>3</sup> for the interionic and intraionic potentials within ionic molecular crystals. The details of this approach are described elsewhere.<sup>2</sup> In this paper we only outline the method to highlight points specific to the systems under consideration.

The method starts from the quantum chemistry optimization performed for the whole molecular ion  $\text{N}_3^-$ , using the GAUSSIAN94 (Ref. 4) commercial package and Hartree-Fock algorithm with the standard 6-31G\* basis for center and end nitrogens. The resulting molecular charge density is then decomposed onto the nitrogen centers of the  $\text{N}_3^-$  ion in the spirit of a Mulliken population analysis.<sup>5</sup> This determination of the nitrogen ion monopole charges combined with the spherical averaging of the charge distributions enables us to compute the interionic GK pair-potentials. For charge density of the alkali ions we used the Clementi tables.<sup>6</sup>

The intraionic forces are treated within the harmonic approximation whose coefficient are determined by the GAUSSIAN94 package while the long-range Coulomb interactions are computed from the fractional ionicities for the center and end nitrogens: +0.3022 and -0.6511, respectively, and +1 for alkali cations.

## II. ROOM-TEMPERATURE PHASES AND THE ORDER-DISORDER PHASE TRANSITIONS IN $\text{KN}_3$ , $\text{RbN}_3$ , AND $\text{CsN}_3$

The room-temperature phase of  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$  has a body-centered tetragonal structure of space group  $I4/mcm$  ( $Z=4$ ) in which the azide ions are perfectly ordered along two distinctive crystallographic directions.<sup>7,8</sup> This phase is, in fact, the CsCl  $Pm\bar{3}m$  structure tetragonally distorted to allow for the asphericity of the  $\text{N}_3^-$  ions. As the temperature is raised, at ambient pressure,  $\text{RbN}_3$  and  $\text{CsN}_3$  transform at 588 and 424 K, respectively, into a disordered phase and melt at 590 and 599 K.<sup>9</sup> No such transformation has been observed in  $\text{KN}_3$ . The nature and extent of the  $\text{N}_3^-$  disordering as well as the determination of the high-temperature modification of  $\text{RbN}_3$  still remains speculative, whereas the high-temperature phase of  $\text{CsN}_3$  has been reported from x-ray powder diffraction as having  $Pm\bar{3}m$  symmetry.<sup>9</sup> In this phase the linear azide ions are inferred to be oriented at random with respect to the edges of the cubic unit cell.<sup>9</sup> This presumption was more recently supported by Raman-scattering studies in  $\text{RbN}_3$  and  $\text{CsN}_3$ .<sup>10,11</sup>

FIG. 1. Projection along  $c$  of the theoretical structure of  $\text{KN}_3$  in the  $I4/mcm$  phase. Broken lines depict the same structure determined experimentally.

TABLE I. Prototypic atomic positions in the relaxed structures of  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ . Experimental values (Ref. 7) are given in parentheses.

Prototype	$x/a$	$y/b$	$z/c$	Wyckoff
N(2) in $\text{KN}_3$	0.1414(0.1365)	$0.5+0.1414(0.1365)$	0	8( <i>h</i> )
N(2) in $\text{RbN}_3$	0.1376(0.1310)	$0.5+0.1376(0.1310)$	0	8( <i>h</i> )
N(2) in $\text{CsN}_3$	0.1334(0.1260)	$0.5+0.1334(0.1260)$	0	8( <i>h</i> )

### III. STATIC RELAXATION OF THE ROOM-TEMPERATURE $I4/mcm$ PHASES

Using the intraionic and interionic pair potentials obtained as described in Sec. I, we first performed static relaxations for the room-temperature phases of  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ . This procedure determines the positions of atoms and the lattice vectors that correspond to the minimum of the theoretical potential-energy surface, employing a Newton-Raphson-type algorithm. It is performed for an infinite lattice by applying periodic boundary conditions. The standard Ewald technique is used to handle the Coulomb forces.

Supercells, like the  $\text{KN}_3$  supercell shown in Fig. 1, which are equivalent to the crystallographic unit cells for the room-temperature phases of  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$  were used in the minimizations. Table I lists prototype atomic positions as well as the lattice constants obtained by relaxation with the  $I4/mcm$  symmetry constraints for the three azides and compares them with experiment. Agreement between the lattice constants is within 5% for all the azides. An average 5% shortening of the lattice has been a rather general feature observed in our other work with GK potentials.<sup>2</sup> Also, the experimental values of these parameters are room-temperature values and thus include the effects of thermal expansion. For example, as will be shown in the next section, in a molecular-dynamics run on  $\text{KN}_3$ ,  $a$  and  $c$  increase by 0.7% and 2.1%, respectively, between 0–300 K.

The discrepancies in fractional atomic positions are well within the thermal fluctuations of the atoms at room temperature and amount to 2%, 1%, and 1% shortening of the N-N bond lengths in  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ , respectively.

We also performed static relaxations without the  $I4/mcm$

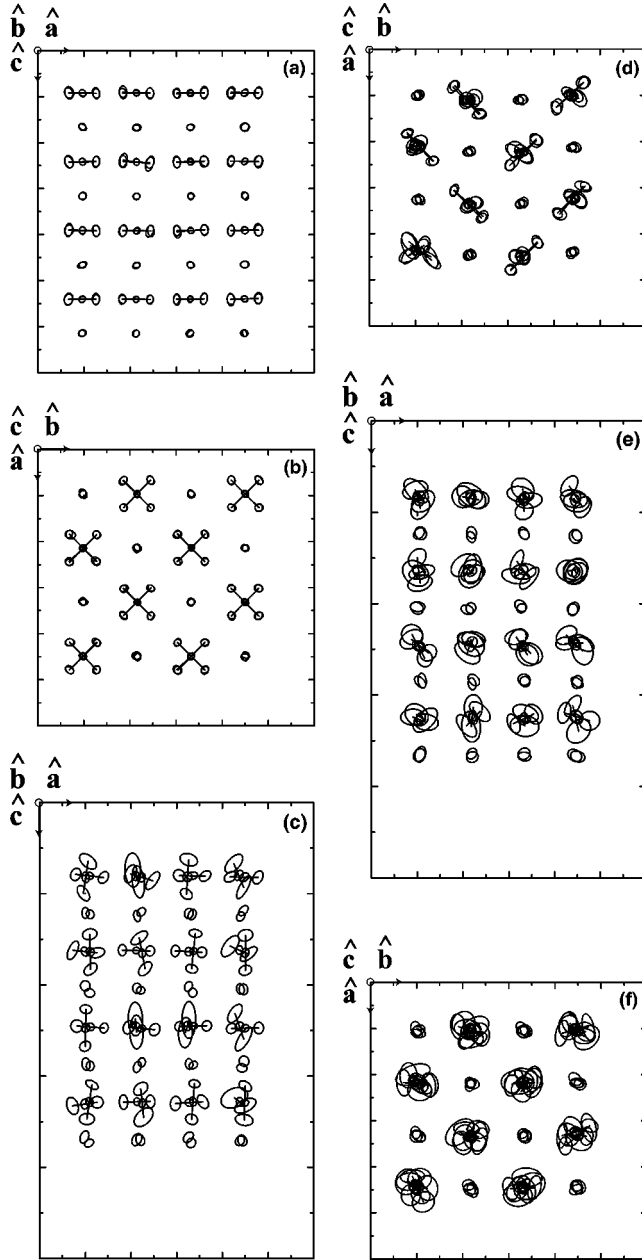

FIG. 2. Projections of the atomic positions along the tetragonal  $b$  and  $c$  axes in the average structure of  $\text{CsN}_3$  obtained from the MD simulation discussed in the text. The “thermal ellipsoids” indicate the rms deviation of atoms from their average positions and represent the thermal motions of the atoms. Bonds connect the average positions of the center nitrogen atoms with the end nitrogen atoms in the  $\text{N}_3^-$  ion. (a,b) 484 K, (c,d) 464 K, and (e,f) 477 K.

FIG. 3. Lattice constants as a function of temperature for the MD run on  $\text{CsN}_3$ . Notice that  $c' = c \equiv \sqrt{2}a = a' = b'$  above  $T_c$ , which indicates the average  $\text{CsCl}$  phase for the disordered  $\text{CsN}_3$ .

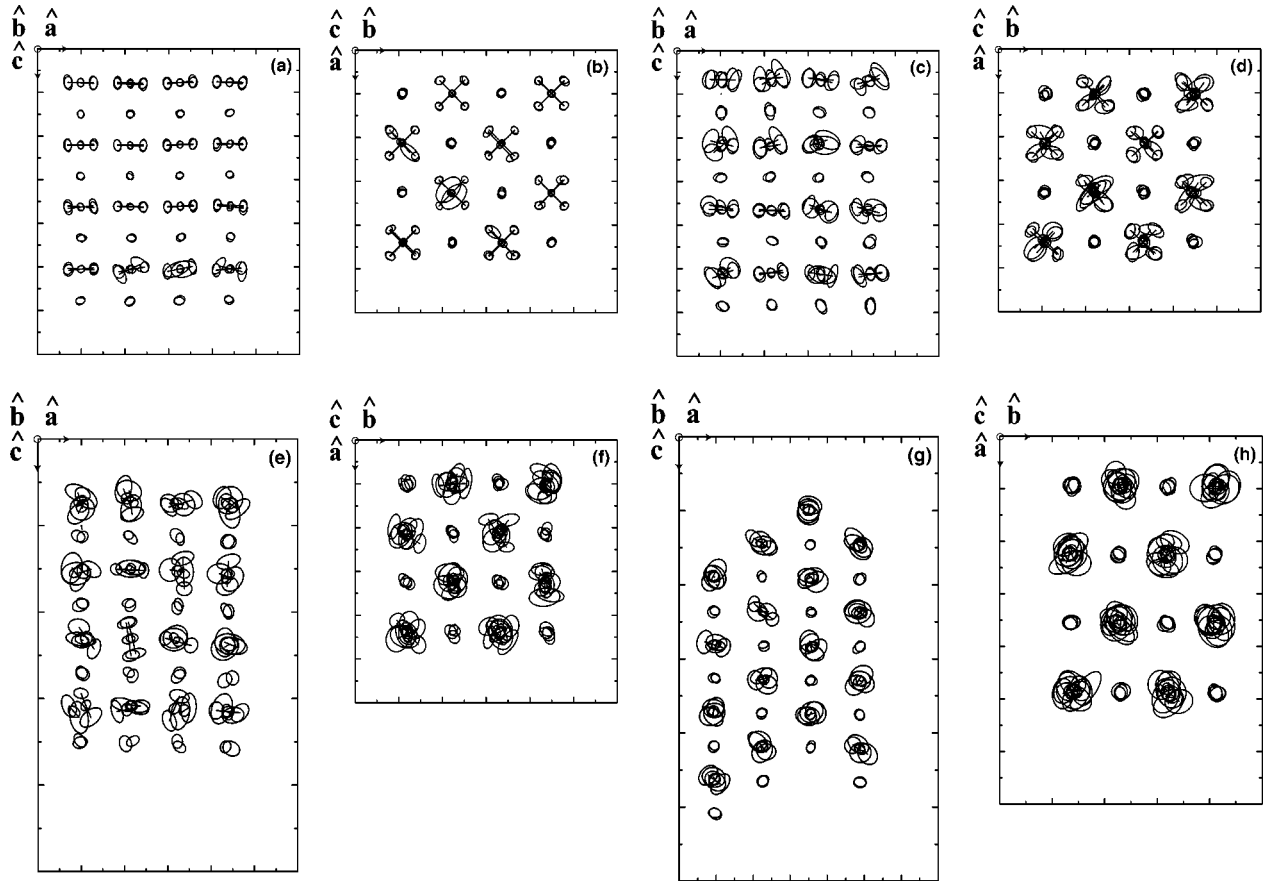

FIG. 4. Projections of the atomic positions along the tetragonal  $b$  and  $c$  axes in the average structure of  $\text{RbN}_3$  obtained from the MD simulation discussed in the text. (a,b) 618 K, (c,d) 613 K, (e,f) 603 K, (g,h) 664 K.

symmetry constraints, and in all cases exactly reproduced the relaxed structures obtained with the symmetry constraints.

#### IV. MOLECULAR-DYNAMICS SIMULATIONS OF THE PHASE TRANSITIONS (REF. 12)

These potentials were then employed in molecular-dynamics simulations. These runs were initiated on 128 atoms supercells obtained from doubling the statically relaxed room-temperature symmetry cells of the three azides in all three directions. Our constant-energy MD follows the Verlet algorithm with periodic boundary conditions and Ewald summation for lattice energy and forces. As the first step we removed any residual energy by “quenching” the supercell to 0 K thus ensuring that a MD run starts from the ground state of the system. Following this “quench,” the system was “heated” by injecting kinetic energy in steps equivalent to  $\sim 5$  K. After each “pulse” the supercell was left to equilibrate for 12 ps. The molecular-dynamics time step used was 0.001 ps and a typical run from 0 to  $\sim 1000$  K on one R10000 @ CPU running at 195 MHz took about two weeks.

We first looked at  $\text{CsN}_3$  as this azide has a well-established high-temperature phase.<sup>9</sup> Figure 2 shows a series of cross sections along two orthogonal directions associated with the  $b$  and  $c$  axes of the *tetragonal* room-temperature unit cell. Figures 2(a) and 2(b) show an ordered system approaching  $T_c$ . Large ovals centered about the atoms represent “thermal ellipsoids,” which indicate rms deviation of

atoms from their average positions. Although, on average, the  $\text{N}_3^-$  ions remain in the  $ab$  plane pointing in the two distinctive directions, as in the room-temperature tetragonal phase, we already notice a tendency among them to move into regions disallowed by the  $14/mcm$  symmetry, namely out of the  $ab$  plane. This tendency becomes more pronounced as the disordering proceeds and in Figs. 2(c) and 2(d) we see half of the  $\text{N}_3^-$  ions rotated  $90^\circ$  from the  $ab$  plane. These ions now progressively occupy space between

FIG. 5. Lattice constants as a function of temperature for the MD run on  $\text{RbN}_3$ . See Fig. 6 for the description of the structural transformation.

FIG. 6. Schematic of the reconstructing of the RbN<sub>3</sub> and KN<sub>3</sub> into the high-temperature average NaCl phase. Black circles denote the center nitrogen atoms of the N<sub>3</sub><sup>-</sup> ions while the end nitrogen were stripped for clarity. The *tetragonal* lattice vectors are drawn only for the room-temperature *I4/mcm* structure (a) and (c). In the high-temperature average *Fm $\bar{3}$ m* structure (d) the new lattice vectors may be assigned along the edges of the cube. The transformation occurs as layers of N<sub>3</sub><sup>-</sup> ions and cations that lie in *bc* planes with distinctive coordinates along *a* direction slide on top of each other and destroy the original room-temperature layered arrangement along the *c* axis in which the N<sub>3</sub><sup>-</sup> ions were sandwiched in between the cations (a). This produces, given the rotational disordering of the N<sub>3</sub><sup>-</sup> ions, the average NaCl structure (b). The CsCl-like unit cell in the room-temperature phase is shown (c) as well as the average NaCl unit cell in the high-temperature phase (d).

the original N<sub>3</sub><sup>-</sup> layers (of the room-temperature tetragonal phase). This causes the lattice to expand along the tetragonal *c* axis as illustrated in Fig. 3, which shows lattice constants as a function of temperature for the MD run on CsN<sub>3</sub>, from *T*=0 K to “melting” at ~1000 K. After the lattice has expanded sufficiently, the N<sub>3</sub><sup>-</sup> ions can perform random hindered rotations about all three spatial axes, as shown in Figs. 2(e) and 2(f). The disordering is now complete and the system has transformed to a new high-temperature phase of the average CsCl symmetry following expansion along *c* and contraction along *a* and *b*.

A more complicated picture emerges for KN<sub>3</sub> and RbN<sub>3</sub>. Figure 4 shows a set of cross sections, along the *b* and *c* axes of the room-temperature tetragonal phase, for the RbN<sub>3</sub> supercell. The cross sections in Fig. 4(a) and 4(b) show the supercell approaching the *T<sub>c</sub>*. The N<sub>3</sub><sup>-</sup> ions are on average still in the ordered state pointing in the two distinctive directions in the *ab* plane. However, in the next cross sections

shown in Figs. 4(c) and 4(d), we see the N<sub>3</sub><sup>-</sup> ions unlocking from their room-temperature positions through hindered rotations, mainly out of the *ab* plane. Next, as shown in Figs. 4(e) and 4(f), hindered rotations in the *ab* plane occur, in addition to those out of the *ab* plane. During this gradual disordering of the N<sub>3</sub><sup>-</sup> ions the lattice expands, as seen in Fig. 5, but does so in a more dramatic way than in case of CsN<sub>3</sub>. We find that the volume change of the supercell above *T<sub>c</sub>* in RbN<sub>3</sub> is ~19% in contrast to ~4% in CsN<sub>3</sub>. In addition to N<sub>3</sub><sup>-</sup> disordering we have a restructuring from a tetragonal phase to an average NaCl phase, as shown in Figs. 4(g) and 4(h). This restructuring is illustrated in Figs. 6(a) and 6(b) while in Figs. 6(c) and 6(d) we show both room-temperature CsCl and high-temperature NaCl unit cells. The appearance of this new high-temperature phase is a novelty in the sense that a structural phase transition of this sort has not been observed experimentally to our knowledge.

A similar behavior was observed in our simulations for

FIG. 7. Projections of the atomic positions along the tetragonal  $a$  and  $c$  axes in the average structures of  $\text{CsN}_3$  obtained from the MD simulation discussed in the text. (a,b) 602 K, (c,d) 561 K, (e,f) 577 K.

$\text{KN}_3$ . Figure 7 shows the cross sections, along the  $a$  and  $c$  axes of the room-temperature tetragonal phase, of the average atomic positions for the  $\text{KN}_3$  supercell as the system undergoes the order-disorder transition. The difference for  $\text{KN}_3$  compared with  $\text{RbN}_3$  is that the transition seems to occur more suddenly with  $\text{N}_3^-$  disordering both in and out of the  $ab$  plane commencing simultaneously, as can be seen in Figs. 7(c) and 7(d). As in the case of  $\text{RbN}_3$ , the disordering of the  $\text{N}_3^-$  ions appears to force a structural transformation from the room-temperature tetragonal phase to a high-temperature average NaCl phase associated with a 16% change in the volume of a supercell. Figure 8 shows lattice constants as a function of temperature for the MD run on  $\text{KN}_3$ .

In any event, isotropic disordering of the  $\text{N}_3^-$  ions should lead to a cubic symmetry in  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ . However, the prototypic simple cubic sublattice of the disordered  $\text{N}_3^-$  ions is intrinsically unstable. Our simulations, in agreement with experiment, show that relatively large  $\text{Cs}^+$  cations can inhibit this instability allowing the lattice to expand in the CsCl prototypic symmetry to the point where it can accommodate the  $\text{N}_3^-$  rotations. For  $\text{RbN}_3$  and  $\text{KN}_3$  our results indicate that this is no longer true.  $\text{Rb}^+$  and  $\text{K}^+$ , being

FIG. 8. Lattice constants as a function of temperature for the MD run on  $\text{KN}_3$ . See Fig. 6 for the description of the structural transformation.

smaller, cannot sufficiently inhibit the intrinsic instability of the  $\text{N}_3^-$  sublattice which, along with the cation sublattice, transforms to the fcc symmetry as the expansion proceeds to allow for the  $\text{N}_3^-$  rotations. This creates the average NaCl high-temperature phase of  $\text{RbN}_3$  and  $\text{KN}_3$ . We found that for  $\text{RbN}_3$  this transformation is somewhat separated from the onset of the  $\text{N}_3^-$  disordering whereas in  $\text{KN}_3$  disordering and restructuring take place simultaneously. In reality, the very large volume change of 19% and 16% associated with these sc  $\rightarrow$  fcc transitions in  $\text{RbN}_3$  and  $\text{KN}_3$  will, at some point, induce melting rather than transformation. [These changes should be compared with the  $\sim 30\%$  change in the volume/ion pair on going from sc  $\rightarrow$  fcc for fixed nearest-neighbor distance. The discrepancy clearly demonstrates that in the sc (CsCl) phase the lattice constant is strongly influenced by  $\text{N}_3^-$ - $\text{N}_3^-$  (second-neighbor) interactions.] The transient, disordered phase found experimentally over 2 K in  $\text{RbN}_3$  (Table II) corresponds to the disordered but not yet transformed phase in our MD runs. Similarly, the absence of the high-temperature disordered phase of  $\text{KN}_3$  in experiment may be explained by the rapid commencement of the restructuring upon the onset of disordering in this material.

## V. CONCLUSION

We have shown that our parameter-free potentials reproduce the room-temperature phases of  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$  to a high degree of accuracy. We subsequently used these potentials in MD runs to study the order-disorder transitions in these materials. Our results show that disordering in all three azides is of the form of hindered rotations about all three axes, and that in  $\text{KN}_3$  and  $\text{RbN}_3$  this disordering is

TABLE II. Calculated and experimental values of  $T_c$  and experimental melting points for  $\text{KN}_3$ ,  $\text{RbN}_3$ , and  $\text{CsN}_3$ . Experimental values are taken from Ref. 9.

associated with restructuring to a new average NaCl phase. However, in the real  $\text{KN}_3$  and  $\text{RbN}_3$  systems the large volume changes induce melting rather than structural transformations. In  $\text{CsN}_3$  the  $\text{N}_3^-$  ions disorder in the prototypic average CsCl phase.
